Governor

October 22, 2004

AFL #04-23

TO: FACILITY ADMINISTRATORS
INFECTION CONTROL PROFESSIONALS

SUBJECT: **Influenza Outbreaks in Healthcare Facilities**

Enclosed are the *Recommendations for the Prevention, Detection, and Control of Influenza in California Long-Term Care Facilities*, revised for the 2004-2005 influenza season, which take into account information on the vaccine shortage current as of October 22, 2004. Influenza outbreaks occur during the winter months, and as a result, about 2,000 Californians die each year. Influenza is a particularly serious problem in nursing homes where residents are at high risk of developing serious complications or dying due to their age and health problems. Once the virus enters a nursing home, it can spread rapidly. During nursing home outbreaks more than half of the residents can become infected, and some require hospitalization or die. The impact of influenza on long-term care facilities may be made worse this season by the vaccine shortage. This makes it particularly important for the Department of Health Services and local health departments to be immediately notified of outbreaks of respiratory illness in healthcare facilities. We can provide assistance in: (1) laboratory testing to determine the cause (outbreaks of respiratory illness may be caused by other pathogens); (2) taking measures to control the outbreak, and (3) obtaining influenza antiviral medications or vaccine. California regulations require that any outbreak of illness in a healthcare facility be reported to both the local health department and the Department of Health Services Licensing and Certification district office.

Annual vaccination is the primary method for preventing influenza and its complications. Influenza vaccine is strongly recommended for BOTH residents and healthcare workers in long-term care facilities. Healthcare workers need to be vaccinated to decrease the risk of transmitting infection to others; vaccination also reduces lost work time. *Please encourage your staff to get vaccinated against the flu.* As vaccine becomes available, both residents of nursing homes and other chronic-care facilities and healthcare workers who provide direct, hands-on care to patients should be vaccinated. FluMist®, the nasal-spray flu vaccine, is an option for healthy individuals, ages 5 to 49 years of age, and may be used as a substitute for standard flu vaccine for healthcare workers in long-term care facilities. All residents should also receive pneumococcal vaccination for *Streptococcus pneumoniae*, since deaths from influenza are often due to bacterial pneumonia that follows influenza.

Influenza antiviral medications can be an important component in the prevention and treatment of influenza. In the setting of the current vaccine shortage, CDC has developed interim recommendations on the use of antiviral medications, and these are included in our recommendations. The California Department of Health Services may be able to assist healthcare facilities to obtain antiviral medications.

The California Adult Immunization Coalition was established in June of 2002. Over 20 organizations committed to developing a long-term, strategic, and integrated effort to improve adult immunization rates for adults who are underserved, at risk and/or have limited access to preventive care services in California. One component of this effort is an initiative to immunize health care workers against influenza. Information and toolkits to assist acute care and long-term care healthcare facilities immunize health care workers is available at the California Adult Immunization Coalition website at: <http://immunizecaadults.org/>.

The Department of Health Services encourages facility staff to review these recommendations, which are intended to be advisory only. There is a new toll-free CDHS Flu Vaccine Information Line: 866-470-3788. This information line will be updated quickly as information becomes available. Questions regarding the use of influenza vaccine should be directed to the Immunization Branch at (510) 540-2065. All questions regarding outbreak control should be referred to Jon Rosenberg M.D., Division of Communicable Disease Control at (510) 540-3233. Written comments about the information contained in these recommendations should be addressed to Dr. Rosenberg, Department of Health Services, Division of Communicable Disease Control, 2151 Berkeley Way, Berkeley, CA 94704.

A handwritten signature in black ink, appearing to read "Jon Rosenberg".

RECOMMENDATIONS FOR THE PREVENTION, DETECTION, AND CONTROL OF INFLUENZA IN CALIFORNIA LONG-TERM CARE FACILITIES, 2004-2005

This report updates the 2003-2004 recommendations regarding the prevention, detection, and control of influenza outbreaks in California long-term healthcare facilities. These recommendations were developed by the California Department of Health Services, Division of Communicable Disease Control, using information from the Centers for Disease Control and Prevention (CDC), in consultation with the Licensing and Certification Program, and are revised annually. This information is intended to be advisory only and was developed to assist facility infection control committees in the development of a rational approach to the control of influenza in long-term healthcare facilities.

These recommendations have been revised to take into account information on the vaccine shortage current as of October 22, 2004. Up to date information and recommendations can be obtained at <http://www.dhs.ca.gov/ps/dcdc/izgroup/flu.htm> and <http://www.cdc.gov/flu/>. The toll-free CDHS Flu Vaccine Information Line is 866-470-3788. The recommendations are based on the Advisory Committee on Immunization Practices (ACIP), "Prevention and Control of Influenza." Comprehensive recommendations for immunizations in long-term care facilities "Prevention and Control of Vaccine-Preventable Diseases in Long-Term Care Facilities," are available at (<http://www.cdc.gov/nip/publications/Long-term-care.pdf>). The absence or shortage of influenza vaccine may result in increased reliance on influenza antiviral medications. CDC interim guidelines for the use of these medications are in Appendix 5, and at <http://www.cdc.gov/flu/professionals/treatment/0405antiviralguide.htm>.

What Is Influenza?

Influenza, commonly called “the flu”, is a respiratory illness caused by influenza type A or type B viruses. Typical symptoms of influenza include fever, respiratory symptoms (such as cough, sore throat, and other “cold” symptoms), muscle aches and headache. Most young, healthy people who get influenza recover completely within 1-2 weeks. Older people and those with certain chronic diseases are much more likely to develop serious medical complications or die following influenza. Influenza is a particularly serious problem in nursing homes. Because of their age and health problems, nursing home residents are at high risk of developing serious complications or dying when they get influenza. They may also be at high risk of exposure to influenza, since the virus spreads more easily in environments where people live close to each other. Once the virus enters a nursing home, it can spread rapidly. During nursing home outbreaks more than half of the residents may be infected, and many may be hospitalized or die. Influenza typically occurs annually in the winter between October and April; peak activity in a community usually lasts from 6 to 8 weeks, historically spanning the New Year period. These recommendations are being issued in anticipation of possible influenza outbreaks in California long-term care facilities this season.

What Was the Influenza Season Like in California the Preceding Year?

Overall, influenza activity in the 2003-2004 influenza season peaked earlier than in previous years and became widespread rapidly. The overall magnitude of influenza activity in California was higher than that of recent previous seasons, but not as high as that seen in the 1997-1998 and 1999-2000 influenza seasons. This season was characterized by the predominance of influenza A strain, A/Fujian/411/2002-like (H3N2) that was not included in the 2003-2004 influenza vaccine. The findings from two studies in Colorado indicated that the influenza vaccine was about 50% effective in preventing illness during the 2003--04 influenza season. Nationally, the overall percentage of deaths for pneumonia and influenza exceeded the epidemic threshold for 9 consecutive weeks (weeks 51 through 6, 12/14/03-2/14/04) and peaked at 10.3% during week 1 (1/04/04-1/10/04).

This season was also characterized by outbreaks of avian influenza. In Asia, avian influenza A (H5N1) outbreaks in poultry resulted in the deaths of over 100 million chickens and laboratory confirmed cases in 34 humans, of whom 23 have died (as of March 24, 2004). Additional outbreaks in poultry accompanied by small numbers of additional cases in humans have continued to be reported in Asia throughout the summer and fall of 2004. At present, no evidence of efficient person-to-person transmission of the H5N1 virus has been documented.

This season's influenza vaccine has been modified to match the strains that were circulating last year. However, even with optimal matches outbreaks can still occur among vaccinated groups. Information on influenza activity in California can be accessed at <http://www.dhs.ca.gov/org/ps/dcdc/VRDL/html/FLU/Fluintro.htm>, and for the United States at www.cdc.gov/ncidod/diseases/flu/weeklychoice.htm.

How Is Influenza Transmitted?

Influenza is spread from person-to-person by large droplets of respiratory secretions from an infected person. This occurs when infected persons cough, sneeze, or talk, expelling droplets, which are then directly deposited onto the surfaces of the upper respiratory tracts (nose, throat) of susceptible persons who are near (within 3 feet) the infected person. Transmission also may occur by direct (e.g., person-to-person) or indirect (person-object-person) contact, when a susceptible person picks up the virus on their hands and then touches their nose. Influenza virus can survive for 24-48 hours on nonporous surfaces and 8-12 hours on porous surfaces such as paper or cloth. Airborne transmission, inhalation of small droplets (droplet nuclei) expelled into the air by an infected person coughing, may also occur. However, this route is probably less important than person-to-person spread by either large droplet or contact transmission.

The most important sources of influenza virus are infected persons. Infected persons are most infectious during the first 3 days of illness; however, they can shed the virus beginning the day before, and up to 7 or more days after, onset of symptoms. Children and severely immunodeficient persons may shed virus for longer periods. In addition, infected but asymptomatic persons can shed the virus and potentially be infectious.

How Can Influenza Be Prevented?

Vaccination of persons at high risk for complications of influenza is currently the most effective measure for reducing the illness and deaths from influenza, and should be done each year before the influenza season, beginning in October. When over 60% of residents of a long-term care facility are vaccinated, the risk of outbreaks is reduced. Vaccination levels can be increased through the use of an annual reminder, such as an order form, placed in each resident's chart. Consent for vaccination should be obtained from the resident or a family member at the time of admission to the facility, and all residents and staff should be vaccinated in the fall. Residents admitted during the winter months should be vaccinated when they are admitted. Since the primary source of infection to residents is staff, and the efficacy of vaccination is often reduced in elderly residents, facilities should make a concerted effort to ensure the annual vaccination of staff, also beginning in October. Two recent studies have shown that staff vaccination reduces deaths from respiratory infections in residents. All residents should receive vaccination for *Streptococcus pneumoniae* also, since deaths from influenza are often due to bacterial pneumonia that follows influenza. Information on pneumococcal vaccine and methods of reimbursement for influenza and pneumococcal vaccine are available from the NIP in "Prevention and Control of Vaccine-Preventable Diseases in Long-Term Care Facilities," accessible at (<http://www.cdc.gov/nip/publications/Long-term-care.pdf>).

Will There Be Enough Influenza Vaccine This Year?

Almost half of the nation's flu vaccine will not be delivered this year. Chiron, a major manufacturer of flu vaccine, will not be distributing any influenza vaccine this flu season. Chiron was to make 46-48 million doses vaccine for the United States. Because of the vaccine shortage, recommendations on who should get vaccinated this season have changed. However, these recommendations still include residents of nursing homes and

other chronic-care facilities and healthcare workers who provide direct, hands-on care to patients. Further information on who should get vaccinated this season is available at <http://www.cdc.gov/flu/protect/0405shortage.htm>.

FluMist®, the nasal-spray flu vaccine, is an option for healthy individuals, ages 5 to 49 years of age, and may be used as a substitute for standard flu vaccine for healthcare workers in long-term care facilities. FluMist® is **not** recommended for healthcare workers taking care of severely immunocompromised people when they are in a protective environment and cannot be given to pregnant women.

How Is Influenza Diagnosed?

A person with influenza may not appear or feel different than when infected with many other respiratory illnesses that cause fever. However, during outbreaks where influenza has been confirmed through laboratory tests, it can be presumed that other persons with similar symptoms also have influenza. Therefore, **when a cluster of cases of respiratory illness occurs it is of critical importance to try to establish the diagnosis through laboratory testing. When an outbreak of respiratory illness begins in a nursing home or any healthcare facility, the local health department and Licensing and Certification district office must be notified** (California Code of Regulations Section 72539 and 72541). Health department personnel can provide information about influenza activity in the area and about how to collect specimens and get a diagnosis. Several commercial rapid diagnostic tests are available that can detect influenza viruses within 30 minutes. Some of these rapid tests detect only influenza A viruses, whereas other rapid tests detect both influenza Type A and B viruses but do not distinguish between the two types. These can be performed on nasopharyngeal-swab or nasal-wash specimens. This information can then be used to begin the use of antiviral drugs to prevent the outbreak from spreading. Precise identification of the strain of virus can be made by growing the virus from nasopharyngeal secretions of acutely ill persons. During outbreaks with laboratory-confirmed cases, persons with similar illnesses can be presumed to also have influenza. A rapid antigen test is available in the California Department of Health Services Viral and Rickettsial Disease Laboratory for the investigation of outbreaks. Specimen collection and coordination should be through local health department laboratories.

How Are Influenza Outbreaks Identified and Controlled?

Influenza-like illness is often defined as an abrupt onset of fever (100° F oral or 101° F rectal) and/or complaints of feverishness with or without myalgia, malaise, headache and at least one of the following respiratory symptoms: cough, sore throat or "cold" symptoms (nasal congestion). Because transmission of influenza can be controlled with antiviral agents it is important to differentiate the virus that causes influenza A or B from other common respiratory viruses that cause influenza-like illnesses.

An outbreak is defined as an increase in the incidence (number of new cases per time interval) of illness over baseline. Because influenza is normally a seasonal infection occurring in winter, the number of new cases of influenza occurring in June would be expected to be zero. However in October through April the number of new cases may exceed baseline. When the incidence exceeds baseline (zero) by 2 or 3 cases in as many

days, the facility is most likely experiencing an outbreak. The local health department should be notified for information about the specific strain of influenza circulating in the community, to help guide the facility medical director to recommend the appropriate antiviral medication, if indicated.

A. Disease Surveillance and Outbreak Management Plan.

Long-term care facilities should develop a surveillance and outbreak control management plan prior to the influenza season and designate a professional to be responsible for continuous disease surveillance for influenza-like illness. A team including the medical director, consulting pharmacist and a representative from the clinical laboratory should assist in developing the plan. Distribute the disease surveillance and outbreak management plan to all admitting physicians requesting confirmation that they agree with the plan. If they do not agree with the plan they should indicate this in writing the facility's medical director and administrator. The plan should include:

1. Consultation with the Centers for Disease Control and Prevention (CDC) and the California Department of Health Services, Immunization Branch (see [References and Other Sources of Information, page 9](#)) for annual revisions to influenza vaccination recommendations.
2. Informing new residents, family members, conservators or significant others of the facility's vaccination policy and obtaining a signed consent to vaccinate residents annually.
3. Developing a physician's order form to administer vaccination. This form can be limited to a specific year or can be a blanket consent to vaccinate annually.
Note: The physician's order form should also request vaccination for *Streptococcus pneumoniae* (pneumococcal pneumonia) at the time of admission. This vaccination is generally given only once in a lifetime. If there is no written documentation of previous immunization or contraindications to vaccination, a second vaccination should be given at the time of admission.
4. Maintaining a line listing of all residents vaccinated (influenza and pneumococcal) and those who decline vaccination.
5. Developing a vaccination program for staff members. Provide staff written and verbal information on the importance of vaccination and maintain a line listing of staff members who consent or decline vaccination.
Note: Educational materials can be obtained from the local health officer or the Department of Health Services, Immunization Branch (see [References and Other Sources of Information, page 9](#)).
6. If an influenza outbreak is suspected, offer vaccination to residents and staff who previously declined vaccination.
7. Develop a system for distributing antiviral medication and monitoring for adverse reactions. See Section C, below.
Note: The medical director should be authorized to order antiviral medication for all residents in the facility.

B. When an Influenza Outbreak is Suspected

1. Each nursing unit should immediately report any resident(s) or staff member(s) with symptoms of influenza-like illness to the infection control practitioner. New cases should be reported and recorded daily using the case log ([Appendix 1](#)).
2. The medical director should be notified.
3. Confine symptomatic residents to their rooms (see Droplet Precautions).
4. Request symptomatic staff to stay home until symptoms have subsided.
5. Discontinue "floating" staff from the affected unit to non-affected units, if possible.
6. Request symptomatic family members to avoid visitation until the incidence of new cases has decreased and the medical director authorizes visitation.
7. Monitor residents who required hospitalization and who die during the outbreak. Determine if the hospitalization or death was related to complications of influenza such as pneumonia or attributed to underlying disease, and document vaccine status and the use of influenza antiviral medications.
8. Notify the local health officer and the Licensing and Certification district office with jurisdiction over your facility

C. Confirm Diagnosis by Laboratory Testing

- Notify the laboratory prior to sending specimens for processing. The local health department can assist in recommending the appropriate diagnostic laboratory tests. If rapid antigen tests and/or viral cultures are recommended, determine the appropriate laboratory to process the specimens. If an outbreak is suspected or influenza virus is detected from 1 or more specimens, institute influenza control measures as described below

D. Implement Influenza Control Measures

1. **Cohort** infected residents:
 - a. Keep suspected or confirmed infected residents in a private room or in a room with other residents with the same symptoms.
 - b. Maintain the same staff to resident assignments, if possible.
 - c. Limit staff from floating to non-affected nursing unit, if possible.
2. In addition to Standard Precautions place symptomatic residents on **Droplet Precautions**.
 - a. Wear a surgical mask when within 3 feet of symptomatic residents or when entering the room occupied by more than one symptomatic resident.
 - b. Place a mask over the resident's nose and mouth when leaving the room if transport or movement of resident is necessary.
 - c. Wear gloves when contact with respiratory secretions is anticipated.
 - d. Decontaminate hands with soap and water after ungloved or gloved contact with articles contaminated with respiratory secretions. Waterless hand hygiene products may be used if gloved or ungloved hands have not had contact with respiratory secretions.
 - e. Wear a gown if soiling of clothes with respiratory secretions is anticipated.

3. Cancel or postpone group activities.
4. Limit new admissions until the incidence of new cases has reached zero. Start a summary log if the outbreak lasts more than 1 week ([Appendix 2, page 11](#)). If new admissions are necessary admit resident to a non-infected unit or to a unit that has had no new cases for at least 2 days.
5. Restrict visitors and volunteers.
6. Vaccinate unvaccinated staff and residents if possible, and consult with the local health department to determine if revaccination of staff or residents during the outbreak would be beneficial.

E. Analyze and report data

1. Analyze reports submitted by the nursing units daily.
2. Determine the number of new cases occurring daily and weekly until there no new cases are identified.
3. Determine the infection attack rates for residents and staff (# of infected residents/total number of vaccinated and total of non-vaccinated residents) and (# total number of infected staff/total number of vaccinated and the total number of non-vaccinated staff).
4. Report data to the quality assurance/infection control committee.
5. Review the disease surveillance and outbreak management plan to determine necessary revisions.
6. Make revisions for implementation during the next influenza year.

F. Consider the use of antiviral medication drugs to minimize the effects of infection by influenza virus.

Antiviral drugs for influenza are an important addition to influenza vaccine for the control of influenza outbreaks. While they are not a substitute for vaccination, they should be considered for use when influenza occurs in a population of unvaccinated persons. Four currently licensed agents are available in the United States: amantadine, rimantadine, zanamivir, and oseltamivir. Amantadine and rimantadine can be used for treatment and prophylaxis of influenza type A. Oseltamivir and zanamivir are effective against both type A or B influenza; Oseltamivir can be used for treatment and prophylaxis while zanamivir approved for treatment but not prophylaxis of influenza. For additional information on anti-influenza drugs see [Appendix 4, page 13](#), and [Appendix 5, page 20](#).

When outbreaks of influenza occur in a long-term care facility, and antiviral prophylaxis of high-risk persons and treatment of cases is undertaken, drug administration should begin as early in the outbreak as possible to reduce transmission. Contingency planning is needed to ensure immediate availability and rapid administration of the drugs. This might include obtaining prior approval from personal physicians for administration of antiviral drugs to residents in the event of an outbreak. Since it is difficult to know in advance how long antiviral drugs will need to be administered, some nursing homes have a policy that also allows facility staff or a consultant to decide when they should be discontinued.

When institutional outbreaks occur, chemoprophylaxis should be administered to all residents - regardless of whether they received influenza vaccine during the previous fall - and should continue for at least 2 weeks or until approximately 1 week after the end of the outbreak. The dosage for each resident should be determined individually.

Chemoprophylaxis also can be offered to unvaccinated staff that provide care to persons at high risk. Prophylaxis should be considered for all employees, regardless of their vaccination status, if the outbreak is caused by a variant strain of influenza A that is not well matched by the vaccine.

To limit the potential transmission of drug-resistant virus during institutional outbreaks, whether in chronic or acute-care settings or other closed settings, measures should be taken to reduce contact as much as possible between persons taking antiviral drugs for treatment and other persons, including those taking chemoprophylaxis.

1. Immediately upon confirmation of influenza, consider the use of antivirals prevent further spread of influenza viruses.
 - a. Immediately upon confirmation of influenza A, consider the use of amantadine or rimantadine.
 - i. Both rimantadine and amantadine are 70 - 90% effective in preventing influenza A when used for prophylaxis. When used prophylactically they should be administered for at least 2 weeks or until approximately 1 week after the last case of ILI. Rimantadine has fewer side effects but is also more expensive than amantadine. Early administration of these medications during influenza A outbreaks has been effective in limiting them.
 - ii. Rimantadine and amantadine can be used for treatment of influenza A infections in three to five day regimens. Treatment of influenza A infections with antiviral medications can reduce the number of days of illness and fever by as much as 50%, and reduce further transmission of influenza **if treatment is started within the first 2 days after illness onset.**
 - b. Immediately upon confirmation of influenza A or B, consider the use of oseltamivir or zanamivir.
 - i. Zanamivir or oseltamivir can be used for the treatment of both, influenza A and B infections. Zanamivir can reduce the duration of influenza symptoms when started **within the first 2 days of illness onset** and is administered as 2 oral inhalations twice a day for 5 days.
 - ii. Oseltamivir has been approved for prophylaxis, but community studies of healthy adults indicate that both drugs are about 80-85% effective in influenza illness.
 - c. Antivirals may be considered for prophylaxis of nursing home staff who have been vaccinated less than 2 weeks prior to outbreak, or who have not been vaccinated.

- d. Separate symptomatic patients on antiviral treatment from others to the extent possible in the facility to decrease the possibility of transmitting antiviral-resistant influenza.
- e. Monitor adverse reactions to antivirals using the format of [Appendix 3, page 12](#). Side effects can include disturbances of the central nervous system such as, confusion and dizziness as well as gastrointestinal disturbances.
- f. Exercise precaution when administering rimantadine or amantadine to persons with:
 - decreased renal function (adjust the dose based on creatinine clearance)
 - liver dysfunction
 - seizure disorders
- g. Note: For a more detailed description on dosing, drug-drug interactions, side effects and contraindications of the use of anti-influenza drugs, see [Appendix 4, page 13](#). Also consult the package inserts for these drugs.

Appendix 4. Antiviral Drugs

(from Reference 1)

Four licensed influenza antiviral agents are available in the United States: amantadine, rimantadine, zanamivir, and oseltamivir. Amantadine and rimantadine are chemically related antiviral drugs known as adamantanes with activity against influenza A viruses but not influenza B viruses. Amantadine was approved in 1966 for chemoprophylaxis of influenza A (H2N2) infection and was later approved in 1976 for treatment and chemoprophylaxis of influenza type A virus infections among adults and children aged ≥ 1 years. Rimantadine was approved in 1993 for treatment and chemoprophylaxis of infection among adults and prophylaxis among children. Although rimantadine is approved only for chemoprophylaxis of infection among children, certain experts in the management of influenza consider it appropriate for treatment among children.

Zanamivir and oseltamivir are chemically related antiviral drugs known as neuraminidase inhibitors, which inhibit neuraminidase and have activity against both influenza A and B viruses. Both zanamivir and oseltamivir were approved in 1999 for treating uncomplicated influenza infections. Zanamivir is approved for treating persons aged ≥ 7 years, and oseltamivir is approved for treatment for persons aged ≥ 1 years. In 2000, oseltamivir was approved for chemoprophylaxis of influenza among persons aged ≥ 13 years.

The four drugs differ in terms of their pharmacokinetics, side effects, routes of administration, approved age groups, dosages, and costs. An overview of the indications, use, administration, and known primary side effects of these medications is presented in the following sections. Information contained in this report might not represent FDA approval or approved labeling for the antiviral agents described. Package inserts should be consulted for additional information.

Indications for Use

Treatment

When administered within 2 days of illness onset to otherwise healthy adults, amantadine and rimantadine can reduce the duration of uncomplicated influenza A illness, and zanamivir and oseltamivir can reduce the duration of uncomplicated influenza A and B illness by approximately 1 day compared with placebo. More clinical data are available concerning the efficacy of zanamivir and oseltamivir for treatment of influenza A infection than for treatment of influenza B infection. However, in vitro data and studies of treatment among mice and ferrets, in addition to clinical studies, have documented that zanamivir and oseltamivir have activity against influenza B viruses.

None of the four antiviral agents has been demonstrated to be effective in preventing serious influenza-related complications (e.g., bacterial or viral pneumonia or exacerbation of chronic diseases). Evidence for the effectiveness of these four antiviral drugs is based principally on studies of patients with uncomplicated influenza. Data are limited and inconclusive concerning the effectiveness of amantadine, rimantadine, zanamivir, and oseltamivir for treatment of influenza among persons at high risk for serious complications of influenza. Fewer studies of the efficacy of influenza antivirals have been conducted among pediatric populations compared with adults.

To reduce the emergence of antiviral drug-resistant viruses, amantadine or rimantadine therapy for persons with influenza A illness should be discontinued as soon as clinically warranted, typically after 3--5 days of treatment or within 24--48 hours after the disappearance of signs and symptoms. The recommended duration of treatment with either zanamivir or oseltamivir is 5 days.

Chemoprophylaxis

Chemoprophylactic drugs are not a substitute for vaccination, although they are critical adjuncts in the prevention and control of influenza. Both amantadine and rimantadine are indicated for the

chemoprophylaxis of influenza A infection, but not influenza B. Both drugs are approximately 70%--90% effective in preventing illness from influenza A infection. When used as prophylaxis, these antiviral agents can prevent illness while permitting subclinical infection and the development of protective antibody against circulating influenza viruses. Therefore, certain persons who take these drugs will develop protective immune responses to circulating influenza viruses. Amantadine and rimantadine do not interfere with the antibody response to the vaccine. Both drugs have been studied extensively among nursing home populations as a component of influenza outbreak control programs, which can limit the spread of influenza within chronic care institutions.

Among the neuraminidase inhibitor antivirals, zanamivir and oseltamivir, only oseltamivir has been approved for prophylaxis, but community studies of healthy adults indicate that both drugs are similarly effective in preventing febrile, laboratory-confirmed influenza illness (efficacy: zanamivir, 84%; oseltamivir, 82%). Both antiviral agents have also been reported to prevent influenza illness among persons given chemoprophylaxis after a household member was diagnosed with influenza. Experience with prophylactic use of these agents in institutional settings or among patients with chronic medical conditions is limited in comparison with the adamantanes. One 6-week study of oseltamivir prophylaxis among nursing home residents reported a 92% reduction in influenza illness. Use of zanamivir has not been reported to impair the immunologic response to influenza vaccine. Data are not available on the efficacy of any of the four antiviral agents in preventing influenza among severely immune compromised persons.

When determining the timing and duration for administering influenza antiviral medications for prophylaxis, factors related to cost, compliance, and potential side effects should be considered. To be maximally effective as prophylaxis, the drug must be taken each day for the duration of influenza activity in the community. However, to be most cost-effective, one study of amantadine or rimantadine prophylaxis reported that the drugs should be taken only during the period of peak influenza activity in a community.

Persons at High Risk Who Are Vaccinated After Influenza Activity Has Begun.

Persons at high risk for complications of influenza still can be vaccinated after an outbreak of influenza has begun in a community. However, the development of antibodies in adults after vaccination can take approximately 2 weeks. When influenza vaccine is administered while influenza viruses are circulating, chemoprophylaxis should be considered for persons at high risk during the time from vaccination until immunity has developed. Children aged <9 years who receive influenza vaccine for the first time can require 6 weeks of prophylaxis (i.e., prophylaxis for 4 weeks after the first dose of vaccine and an additional 2 weeks of prophylaxis after the second dose).

Persons Who Provide Care to Those at High Risk.

To reduce the spread of virus to persons at high risk during community or institutional outbreaks, chemoprophylaxis during peak influenza activity can be considered for unvaccinated persons who have frequent contact with persons at high risk. Persons with frequent contact include employees of hospitals, clinics, and chronic-care facilities, household members, visiting nurses, and volunteer workers. If an outbreak is caused by a variant strain of influenza that might not be controlled by the vaccine, chemoprophylaxis should be considered for all such persons, regardless of their vaccination status.

Persons Who Have Immune Deficiency.

Chemoprophylaxis can be considered for persons at high risk who are expected to have an inadequate antibody response to influenza vaccine. This category includes persons infected with HIV, chiefly those with advanced HIV disease. No published data are available concerning possible efficacy of chemoprophylaxis among persons with HIV infection or interactions with other drugs used to manage HIV infection. Such patients should be monitored closely if chemoprophylaxis is administered.

Other Persons. Chemoprophylaxis throughout the influenza season or during peak influenza activity might be appropriate for persons at high risk who should not be vaccinated. Chemoprophylaxis can also be offered to persons who wish to avoid influenza illness. Health-care providers and patients should make this decision on an individual basis.

Table 1. Recommended adult daily dosage of antiviral medication for treatment and prophylaxis

Antiviral agent	Age Group ¹	
	13-64 years	≥65 years
Amantadine²		
Treatment Influenza A	100 mg twice daily	≤100 mg/day
Prophylaxis Influenza A	100 mg twice daily	≤100 mg/day
Rimantadine³		
Treatment Influenza A	100 mg twice daily	100 mg/day
Prophylaxis Influenza A	100 mg twice daily	100 mg/day
Zanamivir⁴		
Treatment	10 mg twice daily	10 mg twice daily
Oseltamivir⁵		
Treatment	75 mg twice daily	75 mg twice daily
Prophylaxis	75 mg/day	75 mg/day

¹ For ages less than 14 years consult drug package insert.

² The drug package insert should be consulted for dosage recommendations for administering amantadine to persons with creatinine clearance ≤50mL/min/1.73m².

³ A reduction in dose to 100mg/day of rimantadine is recommended for persons who have severe hepatic dysfunction or those with creatinine clearance ≤10mL/min. Other persons with less severe hepatic or renal dysfunction taking >100mg/day of rimantadine should be observed closely, and the dosage should be reduced or the drug discontinued, if necessary.

⁴ Zanamivir is administered via inhalation using a plastic device included in the package with the medication. Patients will benefit from instruction and demonstration of the correct use of the device. Zanamivir is not approved for prophylaxis.

⁵ A reduction in the dose of oseltamivir is recommended for persons with creatinine clearance <30 mL/min.

Persons Aged ≥65 Years

Amantadine. The daily dosage of amantadine for persons aged ≥65 years should not exceed 100 mg for prophylaxis or treatment, because renal function declines with increasing age. For certain older persons, the dosage should be further reduced.

Rimantadine. Among older persons, the incidence and severity of central nervous system (CNS) side effects are substantially lower among those taking rimantadine at a dosage of 100 mg/day than among those taking amantadine at dosages adjusted for estimated renal clearance. However, chronically ill older persons have had a higher incidence of CNS and gastrointestinal symptoms and serum concentrations two to four times higher than among healthy, younger persons when rimantadine has been administered at a dosage of 200 mg/day.

For prophylaxis among persons aged ≥65 years, the recommended dosage is 100 mg/day. For treatment of older persons in the community, a reduction in dosage to 100 mg/day should be considered if they experience side effects when taking a dosage of 200 mg/day. For treatment of older nursing home residents, the dosage of rimantadine should be reduced to 100 mg/day.

Zanamivir and Oseltamivir. No reduction in dosage is recommended on the basis of age alone.

Persons with Impaired Renal Function

Amantadine. A reduction in dosage is recommended for patients with creatinine clearance ≤ 50 mL/min/1.73m². Guidelines for amantadine dosage on the basis of creatinine clearance are found in the package insert. Because recommended dosages on the basis of creatinine clearance might provide only an approximation of the optimal dose for a given patient, such persons should be observed carefully for adverse reactions. If necessary, further reduction in the dose or discontinuation of the drug might be indicated because of side effects. Hemodialysis contributes minimally to amantadine clearance.

Rimantadine. A reduction in dosage to 100 mg/day is recommended for persons with creatinine clearance ≤ 10 mL/min. Because of the potential for accumulation of rimantadine and its metabolites, patients with any degree of renal insufficiency, including older persons, should be monitored for adverse effects, and either the dosage should be reduced or the drug should be discontinued, if necessary. Hemodialysis contributes minimally to drug clearance.

Zanamivir. Limited data are available regarding the safety and efficacy of zanamivir for patients with impaired renal function. Among patients with renal failure who were administered a single intravenous dose of zanamivir, decreases in renal clearance, increases in half-life, and increased systemic exposure to zanamivir were observed. However, a limited number of healthy volunteers who were administered high doses of intravenous zanamivir tolerated systemic levels of zanamivir that were substantially higher than those resulting from administration of zanamivir by oral inhalation at the recommended dose. On the basis of these considerations, the manufacturer recommends no dose adjustment for inhaled zanamivir for a 5-day course of treatment for patients with either mild-to-moderate or severe impairment in renal function.

Oseltamivir. Serum concentrations of oseltamivir carboxylate (GS4071), the active metabolite of oseltamivir, increase with declining renal function (201,204). For patients with creatinine clearance of 10–30 mL/min (201), a reduction of the treatment dosage of oseltamivir to 75 mg once daily and in the prophylaxis dosage to 75 mg every other day is recommended. No treatment or prophylaxis dosing recommendations are available for patients undergoing routine renal dialysis treatment.

Persons with Liver Disease

Amantadine. No increase in adverse reactions to amantadine has been observed among persons with liver disease. Rare instances of reversible elevation of liver enzymes among patients receiving amantadine have been reported, although a specific relationship between the drug and such changes has not been established.

Rimantadine. A reduction in dosage to 100 mg/day is recommended for persons with severe hepatic dysfunction.

Zanamivir and Oseltamivir. Neither of these medications has been studied among persons with hepatic dysfunction.

Persons with Seizure Disorders

Amantadine. An increased incidence of seizures has been reported among patients with a history of seizure disorders who have received amantadine. Patients with seizure disorders should be observed closely for possible increased seizure activity when taking amantadine.

Rimantadine. Seizures (or seizure-like activity) have been reported among persons with a history of seizures who were not receiving anticonvulsant medication while taking rimantadine. The extent to which rimantadine might increase the incidence of seizures among persons with seizure disorders has not been adequately evaluated.

Zanamivir and Oseltamivir. Seizure events have been reported during postmarketing use of zanamivir and oseltamivir, although no epidemiologic studies have reported any increased risk for seizures with either zanamivir or oseltamivir use.

Route

Amantadine, rimantadine, and oseltamivir are administered orally. Amantadine and rimantadine are available in tablet or syrup form, and oseltamivir is available in capsule or oral suspension form. Zanamivir is available as a dry powder that is self-administered via oral inhalation by using a plastic device included in the package with the medication. Patients will benefit from instruction and demonstration of correct use of this device.

Pharmacokinetics

Amantadine. Approximately 90% of amantadine is excreted unchanged in the urine by glomerular filtration and tubular secretion (223,251--254). Thus, renal clearance of amantadine is reduced substantially among persons with renal insufficiency, and dosages might need to be decreased (see Table 1).

Rimantadine. Approximately 75% of rimantadine is metabolized by the liver (218). The safety and pharmacokinetics of rimantadine among persons with liver disease have been evaluated only after single-dose administration (218,255). In a study of persons with chronic liver disease (the majority with stabilized cirrhosis), no alterations in liver function were observed after a single dose. However, for persons with severe liver dysfunction, the apparent clearance of rimantadine was 50% lower than that reported for persons without liver disease.

Rimantadine and its metabolites are excreted by the kidneys. The safety and pharmacokinetics of rimantadine among patients with renal insufficiency have been evaluated only after single-dose administration (218,244). Further studies are needed to determine multiple-dose pharmacokinetics and the most appropriate dosages for patients with renal insufficiency. In a single-dose study of patients with anuric renal failure, the apparent clearance of rimantadine was approximately 40% lower, and the elimination half-life was approximately 1.6-fold greater than that among healthy persons of the same age (244). Hemodialysis did not contribute to drug clearance. In studies of persons with less severe renal disease, drug clearance was also reduced, and plasma concentrations were higher than those among control patients without renal disease who were the same weight, age, and sex.

Zanamivir. In studies of healthy volunteers, approximately 7%--21% of the orally inhaled zanamivir dose reached the lungs, and 70%--87% was deposited in the oropharynx. Approximately 4%--17% of the total amount of orally inhaled zanamivir is systemically absorbed. Systemically absorbed zanamivir has a half-life of 2.5--5.1 hours and is excreted unchanged in the urine. Unabsorbed drug is excreted in the feces.

Oseltamivir

Approximately 80% of orally administered oseltamivir is absorbed systemically (204). Absorbed oseltamivir is metabolized to oseltamivir carboxylate, the active neuraminidase inhibitor, primarily by hepatic esterases. Oseltamivir carboxylate has a half-life of 6--10 hours and is excreted in the urine by glomerular filtration and tubular secretion via the anionic pathway. Unmetabolized oseltamivir also is excreted in the urine by glomerular filtration and tubular secretion.

Side Effects and Adverse Reactions

When considering the use of influenza antiviral medications (i.e., choice of antiviral drug, dosage, and duration of therapy), clinicians must consider the patient's age, weight, and renal function (Table 1), presence of other medical conditions; indications for use (i.e., prophylaxis or therapy); and the potential for interaction with other medications.

Amantadine and Rimantadine. Both amantadine and rimantadine can cause CNS and gastrointestinal side effects when administered to young, healthy adults at equivalent dosages of 200 mg/day. However, incidence of CNS side effects (e.g., nervousness, anxiety, insomnia, difficulty concentrating, and lightheadedness) is higher among persons taking amantadine than among those taking rimantadine. In a 6-week study of prophylaxis among healthy adults, approximately 6% of participants taking rimantadine at a dosage of 200 mg/day experienced ≥ 1 CNS symptoms, compared with approximately 13% of those taking the same dosage of amantadine and 4% of those taking placebo. A study of older persons also demonstrated fewer CNS side effects associated with rimantadine compared with amantadine. Gastrointestinal side effects (e.g., nausea and anorexia) occur in approximately 1%--3% of persons taking either drug, compared with 1% of persons receiving the placebo.

Side effects associated with amantadine and rimantadine are usually mild and cease soon after discontinuing the drug. Side effects can diminish or disappear after the first week, despite continued drug ingestion. However, serious side effects have been observed (e.g., marked behavioral changes, delirium, hallucinations, agitation, and seizures). These more severe side effects have been associated with high plasma drug concentrations and have been observed most often among persons who have renal insufficiency, seizure disorders, or certain psychiatric disorders and among older persons who have been taking amantadine as prophylaxis at a dosage of 200 mg/day. Clinical observations and studies have indicated that lowering the dosage of amantadine among these persons reduces the incidence and severity of such side effects (Table 1). In acute overdosage of amantadine, CNS, renal, respiratory, and cardiac toxicity, including arrhythmias, have been reported. Because rimantadine has been marketed for a shorter period than amantadine, its safety among certain patient populations (e.g., chronically ill and elderly persons) has been evaluated less frequently. Because amantadine has anticholinergic effects and might cause mydriasis, it should not be used for patients with untreated angle closure glaucoma.

Zanamivir In a study of zanamivir treatment of influenza-like illness among persons with asthma or chronic obstructive pulmonary disease where study medication was administered after using a B₂-agonist, 13% of patients receiving zanamivir and 14% of patients who received placebo (inhaled powdered lactose vehicle) experienced a >20% decline in forced expiratory volume in 1 second (FEV₁) after treatment. However, in a study of persons with mild or moderate asthma who did not have influenza-like illness, 1 of 13 patients experienced bronchospasm after administration of zanamivir. In addition, during postmarketing surveillance, cases of respiratory function deterioration after inhalation of zanamivir have been reported. Certain patients had underlying airways disease (e.g., asthma or chronic obstructive pulmonary disease). Because of the risk for serious adverse events and because the efficacy has not been demonstrated among this population, zanamivir is generally not recommended for treatment for patients with underlying airway disease. If physicians decide to prescribe zanamivir to patients with underlying chronic respiratory disease after carefully considering potential risks and benefits, the drug should be used with caution under conditions of proper monitoring and supportive care, including the availability of short-acting bronchodilators. Patients with asthma or chronic obstructive pulmonary disease who use zanamivir are advised to 1) have a fast-acting inhaled bronchodilator available when inhaling zanamivir and 2) stop using zanamivir and contact their physician if they develop difficulty breathing. No clear evidence is available regarding the safety or efficacy of zanamivir for persons with underlying respiratory or cardiac disease or for persons with complications of acute influenza. Allergic reactions, including oropharyngeal or facial edema, have also been reported during postmarketing surveillance.

In clinical treatment studies of persons with uncomplicated influenza, the frequencies of adverse events were similar for persons receiving inhaled zanamivir and those receiving placebo (i.e., inhaled lactose vehicle alone). The most common adverse events reported by both groups were diarrhea; nausea; sinusitis; nasal signs and symptoms; bronchitis; cough; headache; dizziness; and ear, nose, and throat infections. Each of these symptoms was reported by <5% of persons in the clinical treatment studies combined.

Oseltamivir. Nausea and vomiting were reported more frequently among adults receiving oseltamivir for treatment (nausea without vomiting, approximately 10%; vomiting, approximately 9%) than among persons receiving placebo (nausea without vomiting, approximately 6%; vomiting, approximately 3%). Among children treated with oseltamivir, 14.3% had vomiting, compared with 8.5% of placebo recipients. Overall, 1% discontinued the drug secondary to this side effect, whereas a limited number of adults enrolled in clinical

treatment trials of oseltamivir discontinued treatment because of these symptoms. Similar types and rates of adverse events were found in studies of oseltamivir prophylaxis. Nausea and vomiting might be less severe if oseltamivir is taken with food.

Use During Pregnancy. No clinical studies have been conducted regarding the safety or efficacy of amantadine, rimantadine, zanamivir, or oseltamivir for pregnant women; only two cases of amantadine use for severe influenza illness during the third trimester have been reported. However, both amantadine and rimantadine have been demonstrated in animal studies to be teratogenic and embryotoxic when administered at very high doses. Because of the unknown effects of influenza antiviral drugs on pregnant women and their fetuses, these four drugs should be used during pregnancy only if the potential benefit justifies the potential risk to the embryo or fetus (see package inserts for additional information).

Drug Interactions. Careful observation is advised when amantadine is administered concurrently with drugs that affect CNS, especially CNS stimulants. Concomitant administration of antihistamines or anticholinergic drugs can increase the incidence of adverse CNS reactions. No clinically significant interactions between rimantadine and other drugs have been identified.

Clinical data are limited regarding drug interactions with zanamivir. However, no known drug interactions have been reported, and no clinically important drug interactions have been predicted on the basis of in vitro data and data from studies involving rats.

Limited clinical data are available regarding drug interactions with oseltamivir. Because oseltamivir and oseltamivir carboxylate are excreted in the urine by glomerular filtration and tubular secretion via the anionic pathway, a potential exists for interaction with other agents excreted by this pathway. For example, coadministration of oseltamivir and probenecid resulted in reduced clearance of oseltamivir carboxylate by approximately 50% and a corresponding approximate twofold increase in the plasma levels of oseltamivir carboxylate.

No published data are available concerning the safety or efficacy of using combinations of any of these four influenza antiviral drugs. For more detailed information concerning potential drug interactions for any of these influenza antiviral drugs, package inserts should be consulted.

Antiviral Drug-Resistant Strains of Influenza

Amantadine-resistant viruses are cross-resistant to rimantadine and vice versa. Drug-resistant viruses can appear in approximately one third of patients when either amantadine or rimantadine is used for therapy. During the course of amantadine or rimantadine therapy, resistant influenza strains can replace sensitive strains within 2--3 days of starting therapy. Resistant viruses have been isolated from persons who live at home or in an institution where other residents are taking or have recently taken amantadine or rimantadine as therapy; however, the frequency with which resistant viruses are transmitted and their impact on efforts to control influenza are unknown. Amantadine- and rimantadine-resistant viruses are not more virulent or transmissible than sensitive viruses. The screening of epidemic strains of influenza A has rarely detected amantadine- and rimantadine-resistant viruses.

Persons who have influenza A infection and who are treated with either amantadine or rimantadine can shed sensitive viruses early in the course of treatment and later shed drug-resistant viruses, especially after 5--7 days of therapy. Such persons can benefit from therapy even when resistant viruses emerge.

Resistance to zanamivir and oseltamivir can be induced in influenza A and B viruses in vitro, but induction of resistance requires multiple passages in cell culture. By contrast, resistance to amantadine and rimantadine in vitro can be induced with fewer passages in cell culture. Development of viral resistance to zanamivir and oseltamivir during treatment has been identified but does not appear to be frequent. In clinical treatment studies using oseltamivir, 1.3% of posttreatment isolates from patients aged ≥ 13 years and 8.6% among patients aged 1--12 years had decreased susceptibility to oseltamivir. No isolates with reduced susceptibility

to zanamivir have been reported from clinical trials, although the number of posttreatment isolates tested is limited, and the risk for emergence of zanamivir-resistant isolates cannot be quantified. Only one clinical isolate with reduced susceptibility to zanamivir, obtained from an immunocompromised child on prolonged therapy, has been reported. Available diagnostic tests are not optimal for detecting clinical resistance to the neuraminidase inhibitor antiviral drugs, and additional tests are being developed. Postmarketing surveillance for neuraminidase inhibitor-resistant influenza viruses is being conducted.

Appendix 5. Influenza Antiviral Medications: 2004-05 Interim Chemoprophylaxis and Treatment Guidelines

October 18, 2004

INFLUENZA (FLU)

Influenza antiviral medications are an important adjunct to influenza vaccine in the prevention and treatment of influenza. In the setting of the current vaccine shortage, CDC has developed interim recommendations on the use of antiviral medications for the 2004-05 influenza season. These interim recommendations are provided, in conjunction with previously issued recommendations on use of vaccine, to reduce the impact of influenza on persons at high risk for developing severe complications secondary to infection. The recommendations are not intended to guide the use of these medications in other situations, such as outbreaks of avian influenza. These interim recommendations may be updated as more information on the supply of influenza vaccine and antiviral medications becomes available.

Background

Influenza antiviral medications have long been used to limit the spread and impact of institutional influenza outbreaks. They also are used for treatment and chemoprophylaxis of persons in other settings. In the United States, four antiviral medications (amantadine, rimantadine, oseltamivir, and zanamivir) are approved for treatment of influenza, though limited supplies of zanamivir are currently available. When used for treatment within the first two days of illness, all four antiviral medications are similarly effective in reducing the duration of illness by one or two days. Only three antiviral medications (amantadine, rimantadine, and oseltamivir) are approved for chemoprophylaxis of influenza. **More detailed information about each medication, including dosage and approved persons for use, may be found at <http://www.cdc.gov/flu/professionals/treatment>.**

2004-05 Antiviral Medications Usage Guidelines

CDC is issuing interim recommendations for the use of antiviral medications during the 2004-05 season. Local availability of these medications may vary from community to community, which could impact how these medications should be used.

- 1) CDC encourages the use of **amantadine or rimantadine for chemoprophylaxis** and **use of oseltamivir or zanamivir for treatment** as supplies allow, in part to minimize the development of amantadine resistance among circulating influenza viruses.
- 2) **People who are at high risk of serious complications** from influenza may benefit most from antiviral medications. Therefore, in general, people who fall into these high risk groups should be given **priority for use of influenza antiviral medications**:

October 18, 2004

Page 21 of 3

Influenza Antiviral Medications:

2004-05 Interim Chemoprophylaxis and Treatment Guidelines

(continued from previous page)

Treatment

- Any person experiencing a potentially life-threatening influenza-related illness should be treated with antiviral medications.
- Any person at high risk for serious complications of influenza and who is within the first 2 days of illness onset should be treated with antiviral medications. (Pregnant women should consult their primary provider regarding use of influenza antiviral medications.)

Rimantadine is not approved for treatment of children aged < 13 years. For treatment, these persons should receive amantadine (children aged 1-12), oseltamivir (children aged 1-12), or zanamivir (children aged 7-12).

Chemoprophylaxis

- All persons who live or work in **institutions** caring for people at high risk of serious complications of influenza infection should be given antiviral medications in the event of an institutional outbreak. This includes nursing homes, hospitals, and other facilities caring for persons with immunosuppressive conditions, such as HIV/AIDS. When vaccine is available, vaccinated staff require chemoprophylaxis only for the 2-week period following vaccination. Vaccinated and unvaccinated residents should receive chemoprophylaxis for the duration of institutional outbreak activity. Rapid tests or other influenza tests should be used to confirm influenza as the cause of outbreaks as soon as possible. However, treatment and chemoprophylaxis should be initiated if influenza is strongly suspected and test results are not yet available. Other outbreak control efforts such as cohorting of infected persons, and the practice of respiratory hygiene and other measures also should be implemented.
 - All persons at high risk of serious influenza complications should be given antiviral medications if they are likely to be exposed to others infected with influenza. For example, when a high-risk person is part of a family or household in which someone else has been diagnosed with influenza, the exposed high-risk person should be given chemoprophylaxis for 7 days.
- 3) Antiviral medications can be **considered** in other situations when the available supply of such medications is locally adequate.
- **Chemoprophylaxis** of persons in communities where influenza viruses are circulating, which typically lasts for 6-8 weeks:
 - Persons at high risk of serious complications who are not able to get vaccinated.
 - Persons at high risk of serious complications who have been vaccinated but have not had time to mount an immune response to the vaccine. In adults, chemoprophylaxis should occur for a period of 2 weeks after vaccination. In children aged <9 years, chemoprophylaxis should occur for 6 weeks after the first dose, or 2 weeks after the second dose, depending on whether the child is scheduled to receive one or two doses of vaccine.

Influenza Antiviral Medications:

2004-05 Interim Chemoprophylaxis and Treatment Guidelines

(continued from previous page)

- Persons with immunosuppressive conditions who are not expected to mount an adequate antibody response to influenza vaccine.
 - Health-care workers with direct patient care responsibilities who are not able to obtain vaccine.
 - **Treatment** of infected adults and children aged >1 year who do not have conditions placing them at high risk for serious complications secondary to influenza infection.
- 4) Where the supplies of both influenza vaccine and influenza antiviral medications may not be sufficient to meet demand, CDC does not recommend the use of influenza antiviral medications for chemoprophylaxis of non-high risk persons in the community.

Private Sector Sources of Influenza Antiviral Medications

Pharmaceutical distributors should be contacted directly for availability and procurement of antiviral medications.

Strategic National Stockpile

The United States has a limited supply of influenza antiviral medications stored in the Strategic National Stockpile for emergency situations. Efforts are underway by Health and Human Services to procure additional supplies of antiviral medications. Some of the supply will be held in reserve in the event of an influenza pandemic. However, some of the supply will be made available to States and Territories for use in **outbreak settings**, as might occur in a hospital or long term care facility.

Requesting Influenza Antiviral Medications from the SNS

Influenza antiviral medications in the SNS can be requested **only by State or Territory Health Departments**. Institutions (hospitals or long-term care facilities) experiencing an urgent need for such medications should convey their request to the State or Territory Health Department.

1. The State or Territory Health Department should call (770) 488-7100, the CDC 24/7 emergency number, to make a request for antiviral medications. A logistics plan is being drafted and will be available to all state and territorial health departments in the near future.
2. The State or Territory Health Department should indicate that there is an urgent priority use situation (as defined previously) that can be addressed by use of antiviral medications, and should indicate that all reasonable efforts have been made to procure influenza antiviral medications from private distributors.
